

1. What is the Difference Between = and ==?

The **= operator** is an assignment operator used to assign a value to a variable. The **== operator** is a comparison operator used to check whether two values are equal. The **= operator** does not return a Boolean value, whereas **==** returns either True or False. Both operators serve different purposes in Python.

2. What is the Difference Between == and is?

The **== operator** compares the values of two objects, whereas the **is operator** compares their identities (memory locations). Two objects can have the same value but exist at different memory locations. Therefore, **==** may return True while **is** returns False.

3. Which Operators Return Boolean Values?

Comparison operators, logical operators, identity operators, and membership operators return Boolean values (True or False). They are mainly used in conditional statements and loops. These operators help in decision-making within a program.

4. Can We Use Multiple Operators in a Single Expression?

Yes, Python allows multiple operators in a single expression. Python evaluates the expression according to **operator precedence**. Parentheses can be used to control the order of evaluation. This helps in writing concise and efficient code.

5. Why are Operators Important in Python?

Operators are essential because they allow us to perform calculations, compare values, assign data, and make logical decisions in a program. They simplify coding and improve program readability. Without operators, writing programs would be difficult and inefficient.
